15 Abstract

Multiple high-throughput functional screens in cancer cell lines have generated large 16 amounts of information on drug efficacy in a variety of genomic contexts and cancer 17 lineages. Inconsistencies between datasets have led us to investigate whether these 18 large-scale screens reproduce established clinical drug-gene associations and if genomic 19 features particular to specific genes improve said reproducibility. We evaluated three 20 large-scale, small-molecule drug screens and one CRISPR/Cas9 gene essentiality screen, all 21 within the context of clinical interpretations derived from a new cancer variant annotation 22 resource published by the Variant Interpretation for Cancer Consortium (VICC). We identified low levels of concordance between the three drug screen datasets and clinical drug-gene associations using mutation status, gene expression, and copy number as genomic indicators. Less than half of the clinical drug-gene cancer associations from the

VICC resource were identified in these three drug screen datasets, suggesting a barrier to

translating findings from these large-scale screens into the clinic.

Manuscript Draft

32 Introduction

31

Cancer cell lines are a long-standing model for systematic testing of candidate 33 therapeutics, beginning with the National Cancer Institute 60 (NCI60) assay from the late 34 1980s (M. C. Alley et al., 1988; R. H. Shoemaker, 2006; Stinson et al., 1992), which has 35 been used to screen over 100,000 compounds as of 2010 (Holbeck, Collins, & Doroshow, 2010). Since then, numerous small-molecule and gene essentiality screens of various scales 37 and study aims have been conducted in cell lines, from grouping drugs by the apeutic target similarity (Greshock et al., 2010) to screening only near-haploid cell lines to generate genome-level insights into gene essentiality (T. Wang et al., 2015) to broadly identifying cancer dependencies with large-scale screens in multiple cancer types (McDonald et al., 2017; J. M. McFarland et al., 2018; Meyers et al., 2017; Patel et al., 2017) or select lineages (Heiser et al., 2009; Marcotte et al., 2012; Patel et al., 2017). Despite their widespread use, cancer cell lines are known to have issues with inconsistent naming conventions and contamination (M. Yu et al., 2015), and some cell lines have been shown to vary widely at the genetic level and in response to drug treatment across strains (Ben-David et al., 2018). Additionally, comparisons between cancer cell lines and tumors indicate that cell lines have higher numbers of genomic aberrations (Domcke, Sinha, Levine, Sander, & Schultz, 2013; Mouradov et al., 2014; Neve et al., 2006) and tend to be hypermethylated (Paz et al., 2003; Varley et al., 2013), which could prove an impediment to translating cell line discoveries into the clinic. 51 There have also been debates over consistency between drug screen datasets, namely 52

There have also been debates over consistency between drug screen datasets, namely
the Broad Institute's and Novartis Institutes for Biomedical Research's Cancer Cell Line
Encyclopedia (CCLE) (J. Barretina et al., 2012; T. C. C. L. E. Consortium & Consortium,
2015) and the Genomics of Drug Sensitivity in Cancer (GDSC) from the Cancer Genome
Project at the Wellcome Sanger Institute and the Center for Molecular Therapeutics at

Massachusetts General Hospital Cancer Center (Garnett et al., 2012; Yang et al., 2012).

The GDSC has also been referred to as the Cancer Genome Project (CGP) and the Sanger dataset. Studies have shown that drug-gene interactions matched between CCLE and GDSC exhibited poor correlation and inconsistencies (Haibe-Kains et al., 2013; Jang, Neto, Guinney, Friend, & Margolin, 2014), prompting other groups to join the debate on how best correct for experimental and methodological variation between the original drug screens and subsequent computational analysis (T. C. C. L. E. Consortium & Consortium, 2015; Geeleher, Cox, & Huang, 2016; Geeleher, Gamazon, Seoighe, Cox, & Huang, 2016; Hatzis et al., 2014; Haverty et al., 2016; Safikhani et al., 2016, 2017).

The prevalence and importance of cancer cell lines in large-scale therapeutic research and the apparent inconsistencies between the GDSC and CCLE encouraged us to compare the results from these functional screens to clinical drug-gene associations. An outstanding question concerning studies based on cancer cell lines is whether these the cell line systems can accurately model tumor dynamics or recapitulate clinical cancer vulnerabilities, and many large-scale grants and clinical trials are fundamentally anchored by results from screens conducted in cancer cell lines. Thus, our goal was to evaluate how well these functional screens recapitulate known drug, gene, and tumor type associations that are currently used in clinical decision-making.

To curate an evidence-based list of these clinical biomarkers, we utilized a new oncological data aggregation project conducted by the Variant Interpretation for Cancer Consortium (VICC; https://cancervariants.org/), a Driver Project for the Global Alliance for Genomics and Health (GA4GH) (The Global Alliance for Genomics and Health, 2016). The VICC has curated annotations of known cancer variants at varying levels of evidence from multiple resources (A. H. Wagner et al., 2018): the Precision Medicine Knowledgebase (L. Huang et al., 2016), MolecularMatch (https://www.molecularmatch.com/index.html), OncoKB (Chakravarty et al., 2017), Jackson Labs Clinical Knowledgebase (S. E. Patterson et al., 2016), Clinical Interpretations of Variance in Cancers (CIViC) (Griffith et al., 2017),

and the Cancer Genome Interpreter (CGI) (Tamborero et al., 2018). These harmonized variants are hosted on an ElasticSearch (Kibana v6.0) platform called Genotype to 85 Phenotype (G2P, https://search.cancervariants.org/#*) that allows users to query and filter aggregated evidence from the various databases listed above as well as the GA4GH 87 beacon service (http://beacon-network.org/#/), which yields access to genetic mutation data from over 200 datasets as of 2016 (The Global Alliance for Genomics and Health, 2016). For drug screen datasets, we focus on three well-known, large-scale drug projects: the CCLE and GDSC, which were mentioned above, and the Center for the Science of Therapeutics at the Broad Institute's Cancer Therapeutics Response Portal (CTRP) dataset (Basu et al., 2013; M. G. Rees et al., 2016; B. Seashore-Ludlow et al., 2015). We also analyzed the results from a large-scale CRISPR/Cas9 screen conducted by the Broad Institute's Cancer Dependency Map project (DepMap) using the Avana knockout library (Doench et al., 2016; Meyers et al., 2017), which will address whether gene essentiality screens via CRISPR yield results comparable to functional drug screens.

98 Results

Do small-molecule screens in cancer cell lines recapitulate clinical drug-gene associations?

G2P designed a set of standards for stratifying their database's cancer variant interpretations, ranging from preclinical data at the low-evidence end (level D) to clinically actionable interpretations at the high-evidence end (level A). To test only these clinically actionable associations, we filtered the G2P dataset for only level-A G2P interpretations, of which there were 1,296 (see Methods). All compounds screened within the GDSC, CTRP, and CCLE datasets are considered "small molecules" and are respectively linked to Compound (CID) numbers used for indexing in the PubChem database (https://pubchem.ncbi.nlm.nih.gov/). As a result, non-small molecules, which include

Compound	CID	N_G2P	%
EGFR	SID160769799	1	0.25
pertuzumab	CHEMBL2007641	1	0.25
ipilimumab	CHEMBL1789844	2	0.50
cisplatin	CHEMBL2068237	3	0.75
pembrolizumab	CHEMBL3137343	3	0.75
nivolumab	CHEMBL2108738	4	1.00
trastuzumab	CHEMBL1201585	9	2.24
mAb	CHEMBL2109423	16	3.98
cetuximab	CHEMBL1201577	74	18.41
panitumumab	CHEMBL1201827	75	18.66
NA	NA	214	53.23

Note. N_G2P (%) = number of associated G2P interpretations, % is out of column total; mAb = monoclonal antibody; NA indicates G2P interpretation does not have an associated compound.

proteins and biologics (i.e. monoclonal antibodies), that had level-A G2P evidence could
not be included in our comparisons. Thus, G2P interpretations for which the compound
did not have a matching CID code were excluded from further analysis as were
interpretations that did not have an associated compound, resulting in removal of 402
interpretations (Table 1). It should be noted that cisplatin, a small molecule, was excluded
due to its being indexed with a ChEMBLdb identifier (https://www.ebi.ac.uk/chembl/),
which we did not manually re-index to a CID to avoid accidental mischaracterization.

After filtering, 894 level-A G2P interpretations were carried forward in subsequent 116 analyses, constituting 57 unique drugs and 34 unique genes in 88 distinct level-A 117 combinations (Figure 1A: Pink heatmap). The number of level-A interpretations per drug 118 ranged from 1 to 176 (M = 15.68, SD = 34.63), 1 to 264 (M = 26.24, SD = 61.58) per 119 gene, and for each level-A drug-gene combination, the range was 1 to 103 (M = 10.14, 120 SD = 19.80). These unique drugs, genes, and combinations are hereafter referred to as 121 G2P drugs, G2P genes, and G2P associations. Filtering our screening datasets by these 122 clinical criteria yields panels of potentially clinically relevant omic features. Of the 57 123 unique G2P drugs, 37 of them were screened in at least one of the drug screen datasets, 17 124 drugs were screened in at least two of the three datasets, and only 3 were screened in all three datasets. The remaining 20 un-screened G2P drugs suggests an incompleteness of these drug screens, though these projects frequently release new screening data that may 127 include these drugs in future releases. 128

Using cell-line-specific point mutation annotations from the CCLE, we compared z-score-transformed area under the dose-response curve (AUC) distributions between mutant and wildtype cell lines for all G2P associations tested in the CCLE, CTRP, and GDSC drug screens. Of the 88 G2P associations, data was available for 9 associations in CCLE, 48 in CTRP, and 44 in GDSC. Controlling for a false discovery rate (FDR) < 5%, CCLE yielded no significant correlations (Wilcoxon rank-sum tests, $p_k = 1.2^{-4}$), though the most significant G2P association was selumetinib-KRAS ($p_{adj} = 1.1^{-3}$). In CTRP,

AUC from 3 drug-gene associations correlated with the gene's mutation status $(p_k=2.6^{-3})$: vemurafenib-BRAF $(p_{adj}=5.8^{-9})$, selumetinib-KRAS $(p_{adj}=4.6^{-8})$, and dabrafenib-BRAF $(p_{adj}=8.3^{-5})$. Dabrafenib-BRAF $(p_{adj}=3.2^{-11})$ was the only significant association in GDSC $(p_k=2.6^{-6})$.

(???) Describe why we compare all pairwise combos rather than filtering for just the drug-gene combos in G2P?

140

141

To test for potentially novel drug-gene associations, we conducted similar Wilcoxon rank-sum tests for all pairwise combinations of G2P genes and drugs tested in the three drug screens (Figures 1B: Green heatmaps). At an unadjusted $\alpha = 0.05$, the tests revealed that in CCLE, AUC significantly correlated with mutation status for 14 out of 170 (8.24%) tested drug-gene combinations were significantly different, 93 out of 918 (10.13%) were significantly different for CTRP, and 72 out of 850 (8.47%) for GDSC.

Controlling for a FDR < 5%, selumetinib-BRAF $(p_{adj} = 2.9^{-10})$ was the only 148 significant drug-gene combination tested in CCLE $(p_k = 1.2^{-4})$. CTRP $(p_k = 3.9^{-4})$ 149 yielded 4 significant combinations, one of which was selumetinib-BRAF. There were 2 150 significant G2P associations in the GDSC dataset $(p_k = 2.3^{-4})$. Of all the significant 151 correlations between mutation status and AUC across datasets, the only genes represented 152 were KRAS and BRAF (Figure 1). Of the 5 significant drug-gene associations across 153 datasets, 3 were G2P associations. The remaining 2 associations were selumetinib-BRAF154 and trametinib-KRAS. 155

(???) Trametinib and selumetinib are both *MEK* inhibitors, and pazopanib is a *VEGFR* inhibitor. VEGF signaling can influence the MAPK/ERK signaling pathway, which promotes cell proliferation and survival. This pathway includes *RAS*, *BRAF*, and *MEK* proteins.

However, taking these results as a whole, we observe little concordance between G2P 161 associations and the correlation of mutation status and AUC for said G2P association, 162 suggesting that mutation status alone is not a robust predictor of clinically actionable 163 genetic targets. This led us to examine the correlations between AUC and gene expression 164 and AUC and copy number, two other genomic features that are known to associate with 165 cancer and drug response. We computed Spearman correlation coefficients (r_s) between 166 AUC of each drug-gene association and gene expression (RPKM) and copy number (log₂ 167 ratio) of the gene in the association... (???) need to complete this thought/analysis 168

(???) Cut these next three paragraphs since we cut the analysis, but keep for future reference

169

We compared the distribution of level-A G2P associations (Figure 1A) and the 171 associated p-values from the mutation status comparisons (Figure 1B) with a null 172 distribution of p-values derived from all pairwise combinations of G2P genes and the G2P 173 drugs tested in each dataset, less any of the 88 distinct combinations with G2P 174 interpretations, i.e. the non-gray squares in the right heatmap of Figure 1A (Figure 3A). 175 To formally test concordance between clinically actionable variants and drug screen results. 176 we conducted an independent, two-group t-test to compare the distributions of p-values of 177 drug-gene combinations that either were or were not represented with level-A evidence in 178 G2P, which indicated that the distributions of p-values did not significantly differ for 179 CCLE [t(9) = 0.25, p = 0.81], CTRP [t(51) = 0.85, p = 0.40], nor GDSC [t(47) = -0.56, p]180 = 0.58 (Table 2). This further supports that mutation status is not a robust genomic 181 feature for predicting therapeutic responses. 182

Similar tests were conducted for the distributions of Pearson correlation coefficients
(r) between the number of level-A G2P associations and gene expression (RPKM) and copy
number (log2 ratio) of the gene in the association (Figures 3B-C). Example r derivations
are shown in Figures 2B-C. Absolute values of r were used to simplify extreme values in

both directions for testing. The difference in the CCLE |r| distributions for both gene 187 expression [t(8) = 1.43, p = 0.19] and copy number [t(8) = 2.48, p = 0.23] were 188 non-significant, which is likely explained by the small sample size since only five G2P drugs 189 were screened in the CCLE dataset. For both the CTRP and GDSC screens, |r| values for 190 gene expression correlations were significantly greater for the level-A G2P associations than 191 the null distribution [tCTRP(49) = 3.79, pCTRP < 0.001; tGDSC(44) = 2.97, pGDSC = 192 0.005]. The |r| distributions using copy number were also significantly different for CTRP 193 [t(49) = 2.48, p = 0.017] but not for GDSC [t(44) = 1.95, p = 0.058]. 194

In all three datasets for both level-A G2P associations and null distribution 195 associations, there are more significant |r| values when using gene expression as the 196 genomic feature than when using copy number (Table 2), which corresponds with previous 197 work showing that gene expression is an informative molecular feature when assessing drug 198 sensitivity (Jang et al., 2014; Sirota et al., 2011). Additionally, in all cases, there are more 199 significant r values when using copy number than there are significant p-values from the 200 mutation status comparisons. Though observational, these results suggest an order of 201 predictive robustness for these three genomic features when used in isolation: Gene 202 expression > copy number > mutation status. Additionally, across all three genomic 203 features, CTRP consistently identified a higher percentage of its possible level-A G2P 204 associations than GDSC, and similarly, GDSC identified a higher percentage than CCLE. 205 In the CCLE-GDSC debate, inconsistency between the datasets was attributed to the groups using two very different assays for generating AUC measurements though it was undecided which was more accurate (Haibe-Kains et al., 2013; Jang et al., 2014; Weinstein 208 & Lorenzi, 2013). Our results provide very preliminary evidence that GDSC is more 209 accurate than CCLE in regards to reproducing clinical associations. However, CTRP may 210 be even more accurate than both GDSC and CCLE. 211

Do these pancancer drug-gene associations penetrate to the lineage-specific level?

- What do these correlations with mutation status, gene expression, and copy number look like when you constrict to a specific lineage?
- When you restrict, do the correlations become more distinct?
- Are the lineage-specific results approximately the same as the pancancer results?
- Looking at a histogram of p-values, if the histogram is flat, then nothing is significant (note from meeting on 11/16)
 - KS test results

220

- In the 894 level-A G2P interpretations, there was a wide variation in the specificity of 221 cancer description, ranging from "Waldenström macroglobulinemia" and "hyper eosinophilic advanced syndrome" on the more detailed end to "cancer" on the broad end. 223 Similarly, the drug screen datasets had a wide range in lineage specificity, e.g. CCLE, 224 GTRP, and GDSC all had lineages labeled "leukemia" and "T-cell childhood acute 225 lymphocytic leukemia" and the CRISPR dataset had cell lines labeled "Epstein-Barr 226 virus-related Burkitt lymphoma" and "lymphoma." To more easily conduct comparative 227 analyses in a cancer-specific manner, we developed a more general lineage grouping method 228 derived from the Human Disease Ontology identity codes (DOIDs, 220 http://disease-ontology.org/) (Schriml et al., 2019) assigned to each cell line, yielding 27 230 unique lineage groupings. This custom lineage grouping was included in our harmonized 231 cancer cell line database (see Methods). 232
- In the level-A G2P interpretations, there were 102 unique drug-gene-lineage
 combinations (DGLs), representing seven of our curated cancer lineages: cancer, lung
 cancer, breast cancer, leukemia, thyroid cancer, skin cancer, and ovarian cancer. CCLE had
 data for 9 DGLs, CTRP had data for 61, and GDSC had data for 53, yielding a total of 73
 unique DGLs across all three datasets. Only 7 DGLs were screened in all three datasets.

Prior to correction for an FDR of 5%, 1 DGL, selumetinib-KRAS-lung cancer, was identified in the CCLE screen when using mutation status as a correlate (n = 7, 2 DGLs were not analyzed due to lack of mutation annotations in UGT1A1 in "cancer" lineages), but CTRP (n = 48) and GDSC (n = 39) identified 5 and 4, respectively, in skin cancer, lung cancer, and cancer lineages. After Benjamini-Hochberg FDR correction, none of the datasets yielded significant DGL interactions.

(???) KS test results: Need to flesh out this section

245 (Figure 2)

244

Are CRISPR/Cas9 gene essentiality results comparable to those of functional drug screens?

The CRISPR screen from the Broad Institute reports gene dependency using CERES scores (Meyers et al., 2017), which are generated from sgRNA depletion scores and eliminate bias arising from the effect of copy number variation on Cas9 DNA cleavage. The lower the CERES score, the higher the likelihood that the gene is essential in the associated cell line. Scores are scaled per cell line such that a score of 0 is the median effect of nonessential genes and -1 is the median effect of common core essential genes. Of the 34 G2P genes, only G6PD was not targeted by an sgRNA in the CRISPR dataset.

When we don't account for lineage, Wilcoxon rank-sum tests ($p_k = 4.1^{-17}$, FDR <

 $_{256}$ 5%) revealed that mutations in 1 gene significantly correlated with CERES score: KRAS $_{257}$ $(p_{adj} = 3.7^{-37})$. Gene expression (RPKM) of 13 out of 33 (39.39%, Spearman rank-order correlations) G2P genes significantly correlated with CERES score, as did copy number $_{259}$ (log2-ratio) for 12 out of 33 (36.36%, Spearman rank-order correlations) G2P genes $_{260}$ (Figure 3). We see moderate overlap between these genes whose CERES scores $_{261}$ significantly correlated with gene expression and with copy number (Figure 4). For the

purpose of comparison to the drug screen data, if we treat CRISPR knockdown like a small-molecule drug, then these results are more comprehensive than the results from CCLE, CTRP, and GDSC.

(???) Lineage????

265

282

Are known copy number driven associations recapitulated in the drug and CRISPR screens?

If a gene's response to is copy number driven, we would expect copy number to significantly correlate with AUC and gene essentiality scores, as would gene expression is expression and copy number are associated.

In a lineage-agnostic context of the CRISPR screen, ERBB2 gene essentiality score 271 had significant negative correlations with ERBB2 gene expression ($p = 8.3^{-12}$, $r_s = -0.30$) 272 and ERBB2 copy number ($p=3.8^{-10},\,r_s=-0.27$) (Figure ##2). Notably, gene 273 essentiality of MET, which is known to have copy number alterations in some cancers (An 274 et al., 2014; J. H. Kim, Kim, & Kim, 2018), did not significantly correlate with MET gene 275 expression nor MET copy number. BRCA1 gene essentiality also significantly correlated 276 with both BRCA1 gene expression ($p = 4.7^{-6}$, $r_s = 0.20$) and BRCA1 copy number 277 $(p=1.1^{-3}, r_s=0.14)$. BRCA2 gene essentiality significantly correlated BRCA2 gene 278 expression $(p = 6.6^{-7}, r_s = 0.22)$ but not *BRCA2* copy number.

Which genomic features drive KRAS, EGFR, and BRAF drug-gene associations?

(???) Should we do this?

283 Discussion

Level-A G2P interpretations correspond to clinical evidence that suggests efficacy of 284 gene targets and/or drugs, and this work questions whether these relationships manifest 285 themselves in in vitro drug screens. We have demonstrated that on its own, mutation status 286 is not a robust predictor of drug efficacy and that copy number and gene expression fare 287 better as predictors. However, for these three genomic features in all three datasets, only 288 11.1% (mutation status, 1 of 9, CCLE) to 47.9% (gene expression, 23 of 48, CTRP) (Table 289 2), of the level-A G2P drug-gene associations in the respective dataset were significant at 290 an uncorrected $\alpha = 0.05$. This suggests that while the drug screens successfully identify 291 some clinically relevant drug-gene associations, many associations are also missed, which raises the question of the extent to which clinical researchers can rely on in vitro drug screens when attempting to develop and select therapeutics for cancer patients. 294

These results also highlight the need to account for the complex differences inherent 295 between data generated in clinical scenarios and data captured in highly controlled, 296 artificial in vitro environments. Potential sources of variation and error include the fact 297 that cells growing in a laboratory as opposed to those, even of the same tissue type, 298 growing in a multicellular organism are exposed to differing sets of stressors and signals 299 that can significantly impact intracellular signaling pathways, irrespective of shared 300 genomic profiles. These differences can include, but are not be limited to, immunologic 301 reactions, both adaptive and intrinsic (e.g. cytokine signaling, inflammation), endocrine 302 (e.g. stress hormones), and nervous system stimulation, all of which can have significant 303 downstream implications on cellular behavior in the context of therapeutic efficacy. Similarly, a laboratory environment and in vitro cell culture introduce abnormal growth conditions with respect to extracellular matrix composition, nutrient availability, and cell 306 density, all of which have the potential to alter cellular signaling and thus render a drug 307 ineffective during screening despite would-be in vivo activity.

In the era of precision medicine, the ultimate boon would be that the unique omics 309 signatures of a patient's individual cancer can be used to guide treatment. 310 High-throughput, in vitro screens of targeted cancer agents against cell lines with known 311 omics profiles are beneficial for testing hypotheses concerning the mechanisms of action for 312 these agents and they allow for scalability and systematic screening. However, 313 extrapolating the potential downstream effects of inhibiting a major growth pathway 314 (e.g. MAPK, IP-DAG) to predict the clinical prognosis and progression of a multicellular 315 tumor mass growing in a complex environment, compounded with the cross-reacting effects 316 of tumor genomic heterogeneity, make it a questionable statement that one can safely 317 predict clinical consequences from suppressing a single pathway in a model system, as 318 evidenced by our findings of fewer than half of the known clinical associations in the three 319 drug screen datasets. The benefits of these cancer cell line models, in contrast, lie in their ability to assess the big-picture effects of these agents. In order to fully understand 321 therapeutic drug response, a higher degree of granularity is needed. Additional effort to combine more cell line information such as gene expression, epigenetic profiles, and 323 proteomic data with mutational profiles is essential to improving the efficacy and validity 324 of in vitro cell line screens. Further benefit could be derived from conducting these screens in environments that are more in line with the clinical scenarios we are trying to predict. 326 This would include things such a 3-dimensional cell culture, coculturing with stromal cells 327 to mimic the tumor microenvironment, as well as other modalities that can attempt to 328 better replicate in vivo environments. 329

As a next step to improve the informational granularity of the analysis presented
here, our subsequent goal will be to assess the extent to which these drug-gene associations
are specific to individual cancer cell line lineages, which are available and annotated in the
data sets analyzed within this report. By evaluating how many clinically actionable
associations are identified in these large-scale functional screens, we can begin to address
best practices for translating discoveries from these tumor models into clinical trials.

336 Methods

37 G2P cancer variants

Cancer variants with the highest level of evidence (i.e. level A) in the Genotype to 338 Phenotype (G2P) database were retrieved from the Variant Interpretation for Cancer 339 Consortium (VICC) portal (https://search.cancervariants.org/#*) (A. H. Wagner et al., 340 2018) using a customized JSON-query script. All JSON queries were passed to the 341 available application program interface (API) where a request was made for all drug-gene 342 associations with level-A evidence via the G2P evidence label, 343 i.e. association.evidence label. From manual inspection using G2P's front-end Kibana 344 interface, it was known that, at the time of the last query, 27 November 2018, there were 345 1,297 known level-A associations. Due to the limited request processing capabilities of the 346 G2P JSON API, queries were batched into packets of 10 data points, for a total of 130 347 requests made in succession. Each returned request was processed as JSON object and searched to identify any existing key:value pairs for the following variables: evidence level, 349 mutation, gene, chromosome, start, end, ref, alt, direction, phenotype description, 350 phenotype family, phenotype ID, drug, drug ID, feature names, and sequence ID. For any 351 evidence point where a given key:value pair was not found or unavailable, a value of -1 was assigned. One of the 1,297 level-A entries was irretrievable, yielding a final dataset of 1,296 level-A G2P interpretations, which were stored in a pandas data table and exported in 354 CSV format. The VICC's methods for the harvesting and harmonizing of cancer variants is 355 available in a GitHub repository from Oregon Health & Science University 356 (https://github.com/ohsu-comp-bio/g2p-aggregator). 357

DepMap data retrieval and processing

CRISPR/Cas9, CCLE mutation calls, and CCLE copy number data were all retrieved from the Broad Institute's Cancer Dependency Map (DepMap) Public 18Q4 release via the

```
DepMap data portal (https://depmap.org/portal/download/) (DepMap, 2018). Gene
   expression data was retrieved from the DepMap Public 18Q3 release (Broad DepMap,
362
   2018) from the same data portal. For cell lines with no CCLE annotation, the DepMap
363
   group drew raw copy number and mutation data from whole exome sequencing data
364
   produced by the Wellcome Trust Sanger Institute [Catalogue Of Somatic Mutations In
365
   Cancer (COSMIC, https://cancer.sanger.ac.uk/cell lines) (S. Bamford et al., 2004; S. A.
366
   Forbes et al., 2017); European Genome-phenome Archive (Lappalainen et al., 2015),
367
   accession number EGAD00001001039] and processed the data following the CCLE
   pipelines to ensure consistency.
369
```

CRISPR/Cas9 screen. Gene effect scores for 17,634 genes in 517 cell lines were 370 inferred from a CRISPR/Cas9 (clustered regularly interspaced short palindromic 371 repeats/CRISPR-associated 9) screen using the Broad Institute's Avana knockout library 372 (Doench et al., 2016). The Broad Institute's data processing and screening methods are 373 available from the figshare record (DepMap, 2018) and the original publication of CERES, 374 the algorithm that computes inferred gene dependency scores (Meyers et al., 2017). The 375 DepMap releases new data quarterly, with the current data set being the 18Q4 release. 376 This release has 175 more cell lines than the original data release that was published with CERES (dataset: gene effect.csv, accessed 15 November 2018). 378

To preclude variation in genomic feature calls across the datasets, Mutation calls. 379 we used identical annotations from CCLE for all cell lines screened in the three datasets. 380 The CCLE provided mutation annotations in 19,280 genes across 1,596 cell lines (dataset: 381 depmap 18Q4 mutation calls.csv, accessed 14 November 2018). CCLE called substitutions using MuTect (Cibulskis et al., 2013) and annotated variants using Oncotator (Ramos et al., 2015) and indels using Indelocator (https://software.broadinstitute.org/cancer/cga/indelocator). We filtered mutation calls 385 for point mutations, defined as single-nucleotide insertions, deletions, and substitutions, 386 regardless of result, i.e. frameshift, missense, or nonsense mutation. For this analysis, cell 387

lines harboring non-silent point mutations were considered "mutant" for the gene in
question. All other mutations and genes without annotation in the Mutation Annotation
Format (MAF) file were considered "wildtype." "Mutant" and "wildtype" calls were
binarily encoded per-gene/per-cell line, regardless of quantity of harbored mutations per
gene in a given cell line.

Copy number data. The CCLE generated genomic copy number (CN) data using
the Affymetrix Genome-Wide Human SNP Array 6.0 and GenePattern pipeline (Network,
2008) and normalized segmented CN log2-ratios for 23,299 genes across 1,098 cell lines
using circular binary segmentation (Olshen, Venkatraman, Lucito, & Wigler, 2004)
(dataset: public_18Q4_gene_cn.csv, accessed 15 November 2018).

Gene expression data. The CCLE reports gene expression in RPKM (reads per kilobase per million mapped reads) for 54,356 genes across 1,156 cell lines, generated on the GeneChip Human Genome U133 Plus 2.0 Array (dataset:

CCLE_DepMap_18q3_RNAseq_RPKM_20180718.gct, accessed 18 July 2018).

402 Drug screen dataset retrieval and harmonization

The Cancer Therapeutics Response Portal (CTRP) drug screen dataset (v2) (Basu et 403 al., 2013; M. G. Rees et al., 2016; B. Seashore-Ludlow et al., 2015) was retrieved from the 404 National Cancer Institute's Cancer Target Discovery and Development (CTD2) Network's 405 data portal (https://ocg.cancer.gov/programs/ctd2/data-portal, accessed 6 June 2018). 406 The Genomics of Drug Sensitivity in Cancer (GDSC) drug screen dataset (Garnett et al., 2012; Yang et al., 2012) was retrieved from the data portal at (https://www.cancerrxgene.org/downloads, accessed 19 June 2018). The Cancer Cell Line Encyclopedia (CCLE) drug screen dataset (J. Barretina et al., 2012; T. C. C. L. E. 410 Consortium & Consortium, 2015) was retrieved from the Broad Institute's data portal 411 (https://portals.broadinstitute.org/ccle, accessed 20 June 2018). 412

Cell line harmonization. In an effort to compare CCLE, CTRP, GDSC and 413 CRISPR results and include lineage specificity, it was necessary to consolidate cell lines 414 screened in each dataset. Given that unique identifiers can be used between studies, it was 415 necessary to standardize the identity of each cell line with a common source. To achieve 416 this, a freely available cell line database called Cellosaurus (v26.0, 14 May 2018) (Bairoch, 417 2018) was downloaded and merged with the Broad Institute's DepMap cell line data 418 (accessed 8 June 2018) to create a harmonized cancer cell line database containing 419 synonymous identifiers that enabled consolidation of all cell lines used in CCLE, CTRP, GDSC and CRISPR into a common framework. Subsequent additions to this database 421 include the merging of DepMap IDs used in the 18Q3 and 18Q4 DepMap data releases. We 422 curated missing synonyms and identifiers, and we manually annotated the granularity of 423 lineage labeling for all cell lines analyzed in this study based on their Human Disease Ontology identity codes (DOIDs, http://disease-ontology.org/) (Schriml et al., 2019), 425 resulting in 27 unique lineages. For ease of comparison between datasets, we labeled all cell lines with custom, randomized identifiers. 427

AUC harmonization. The CCLE reports cell line sensitivity to small molecules as
an activity area measured above the dose-response curve (ActArea), while both CTRP and
GDSC report small molecule activity as area under the dose-response curve (AUC). Since
ActArea is reported with a scale of 0 to 8, we converted CCLE's ActArea values to AUC via

$$AUC = 1 - \frac{ActArea}{8}$$

All AUC values across the three drug screen datasets were z-score transformed:

432

$$z = \frac{AUC - \mu_{AUC}}{\sigma_{AUC}}$$

where AUC is the mean AUC across all drug-cell line combinations in the dataset and AUC is the standard deviation.

Computational

449

done and a value of NA was supplied.

```
For Figure 1, all data were imported and manipulated using pandas (v0.23.0)
436
   (McKinney, 2011) and plotted using seaborn (v0.90) (Waskom, 2012), which sat on top of
437
   matplotlib (v2.2.2) (Hunter, 2007) and was executed on Python (v2.7.15) (Python Software
438
   Foundation, https://www.python.org/) in an IPython (v5.5.0) (Pérez & Granger, 2007)
439
   kernel within a localhost Jupyter (v5.2.2) notebook (Kluyver et al., 2016). All other
440
   analyses were conducted in R (v3.5.0) (R. D. C. Team, 2010, https://www.R-project.org/)
   in an RStudio environment (v1.1.447) (RStudio, 2012). All other plots were drawn using
   the ggplot2 (v3.0.0) R package (Wickham, 2016).
         Statistics.
                      Wilcoxon tests were conducted using the compare_means function in
444
   the ggpubr (v0.1.7.999) R package (Kassambara, 2018). compare means does
445
   Benjamini-Hochberg p-value adjustment using the p.adjust function from the stats base

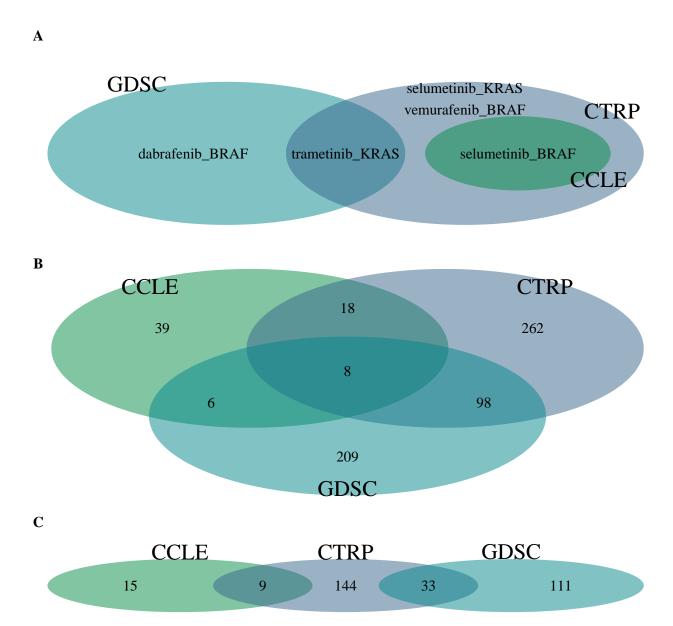

Figure 1. Overlap of significant drug-gene associations from CCLE, CTRP, and GDSC. Overlap of drug-gene associations drawn from all pairwise combinations of G2P drugs and G2P genes whose drug effects significantly correlated with (A) mutation status, (B) gene expression, and (C) copy number across CCLE, CTRP, and GDSC.

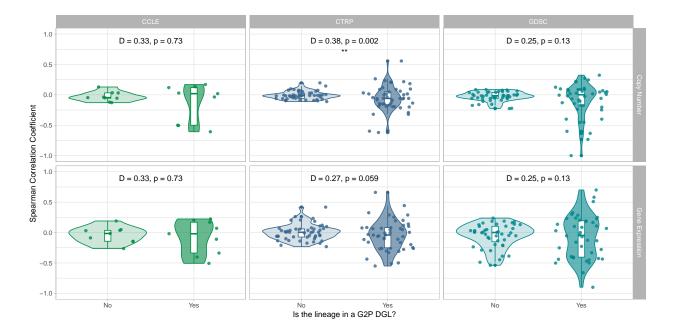

Figure 2. Comparison of drug-gene AUC vs. gene expression and vs. copy number in G2P and non-G2P cell lines. Comparison of Spearman correlation coefficients (r_s) derived from copy number (\log_2 ratio) vs. AUC z-scores and gene expression (RPKM) vs. AUC z-scores for G2P drug-gene associations. Correlation coefficients were grouped by whether or not the associated lineage for each comparison was in a level-A G2P drug-gene-lineage association or not. The distributions of these grouped coefficients were compared using Kolmogorov-Smirnov tests to identify whether correlations in G2P lineages were distinct from correlations in non-G2P lineages.

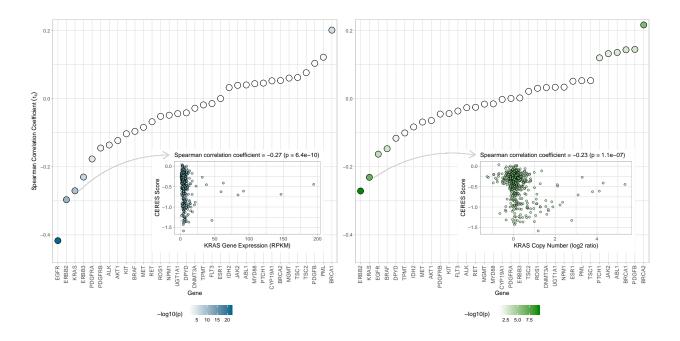

Figure 3. Stuff stuff stuff!

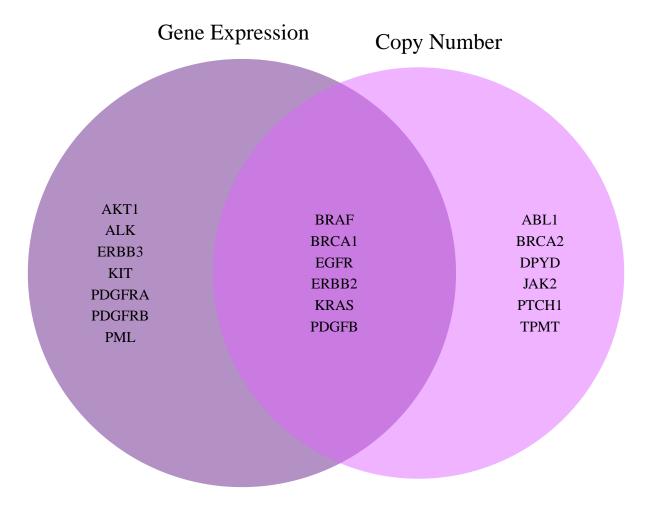

Figure 4. CRISPR sceen results. Overlap of genes whose gene expression and/or copy number significantly correlated with CERES score (Spearman rank-order correlations).
